Realm-Based Spatial Data Types:

The ROSE Algebra[1]

Abstract: Spatial data types or algebras for database systems should (i) be fully general (which means, closed under set operations, hence e.g. a region value can be a set of polygons with holes), (ii) have formally defined semantics, (iii) be defined in terms of finite representations available in computers, (iv) offer facilities to enforce geometric consistency of related spatial objects, and (v) be independent of a particular DBMS data model, but cooperate with any. We offer such a definition. A central idea is to use *realms* as geometric domains underlying spatial data types. A realm as a general database concept is a finite, dynamic, user-defined structure underlying one or more system data types. A geometric realm defined here is a planar graph over a finite resolution grid. Problems of numerical robustness and topological correctness are solved below and within the realm layer so that spatial algebras defined above a realm enjoy very nice algebraic properties. Realms also interact with a DBMS to enforce geometric consistency on object creation or update. The ROSE algebra is defined on top of realms and offers general types to represent point, line, and region features together with a comprehensive set of operations. It is described within a polymorphic type system and interacts with a DBMS data model and query language through an abstract *object model interface*. An example integration of ROSE into the object-oriented data model O_2 and its query language is presented.

Keywords: Spatial data types, algebra, realm, finite resolution, numerical robustness, topological correctness, geometric consistency, object model interface, ROSE.

---

1 Introduction

We consider a *spatial database system* to be a full-fledged DBMS with additional capabilities for the representation and manipulation of geometric data. As such, it provides the database technology needed to support applications such as *geographic information systems*. The standard DBMS view for the organization of spatial information is the following: A database consists of several classes of objects. A *spatial object* is just an object with an associated value ("attribute") of a *spatial data type*, such as, for example, *point*, *line*, or *region*. This is true regardless of whether the DBMS uses a relational, complex object, object-oriented or some other data model. Hence the definition and implementation of spatial data types is probably the most fundamental issue in the development of spatial database systems.

Although spatial data types (SDTs) are used routinely in the description of spatial query languages (e.g. [LiN87, JoC88, SvH91, To90]), have been implemented in some prototype systems (e.g. [RoFS88, OrM88, Gü89]), and some formal definitions have been given [Gü88a, ScV89, GaNT91], there is still no completely satisfactory solution available according to the following criteria:

- *Generality.* The geometric objects used as SDT values should be as general as possible. For example, a region value should be able to represent a collection of disjoint areas each of which may have holes. More precisely, this means that the domains of data types *point*, *line*, and *region* must be closed under union, intersection, and difference of their underlying point sets. This allows for the definition of powerful data type operations with nice closure properties.

- *Rigorous definition*. The semantics of SDTs, that is, the possible values for the types and the functions associated with the operations, must be defined formally to avoid ambiguities for the user and the implementor.

- *Finite resolution*. The formal definitions *must take into account the finite representations available in computers*. This has so far been neglected in definitions of SDTs. It is left to the programmer to close this gap between theory and practice which leads rather inevitably not only to numerical but also topological errors.

- *Treatment of geometric consistency.* Distinct spatial objects may be related through geometric consistency constraints (e.g. adjacent regions have a common boundary). The definition of SDTs must offer facilities to enforce such consistency.

- *General object model interface*. Spatial data types as such are rather useless; they need to be integrated into a DBMS data model and query language. However, a definition of SDTs should be valid regardless of a particular DBMS data model and therefore not depend on it.[2] Instead, the SDT definition should be based on an abstract interface to the DBMS data model which we call the *object model interface*.

The purpose of this paper (together with a companion paper [GüS93]) is to develop a formal definition of spatial data types fulfilling these criteria. A central idea is to introduce into the DBMS the concept of a *realm*. A realm is in general a finite, user defined structure that is used as a basis for one or more system data types. Realms are somewhat similar to enumeration types in programming languages. A realm used as a basis for spatial data types is essentially a finite set of points and *non-intersecting* line

---

[2] This also holds for the implementation level: A spatial type extension package (STEP) should be able to cooperate with any extensible DBMS offering a suitable interface regardless of its data model.

segments. Intuitively, it describes the complete underlying geometry of an application. All points, lines and regions associated with objects (from now on called *spatial attribute values*) can be defined in terms of points and line segments present in the realm. In fact, in a database spatial attribute values are then never created directly but only by selecting some realm objects. They are never updated directly. Instead, updates are performed on the realm and from there propagated to the dependent attribute values.

Hence, all attribute values occurring in a database are *realm-based*. Furthermore, the algebraic operations for the spatial data types are defined to construct only geometric objects that are realm-based as well. So the spatial algebra is closed with respect to a given realm. This means in particular that no two values of spatial data types occurring in geometric computation have "proper" intersections of line segments. Instead, two initially intersecting segments have already been split at the intersection point when they were entered into the realm. One could say that any two intersecting SDT values (say, lines or regions) "have become acquainted" already when they were entered into the realm. This is a crucial property for the correct and efficient implementation of geometric operations.

Realm objects - points and segments - are defined not in abstract Euclidean space but in terms of finite representations. All geometric primitives and realm operations (e.g. updates) are defined in error-free integer arithmetic. For mapping an application's set of intersecting line segments into a realm's set of non-intersecting segments the concept of redrawing and finite resolution geometry from [GrY86] is used. Although intersection points computed with finite resolution in general move away from their exact Euclidean position, this concept ensures that the unavoidable distortion of geometry (that is, the numerical error) remains bounded and very small and that essentially[3] no topological errors occur. This means that a programmer has a precise specification that directly lends itself to a correct implementation. It also means that the spatial algebra obeys algebraic laws precisely in theory as well as in practice. Furthermore, it is rather obvious that realms also solve the geometric consistency problem.

Most closely related to this work are the formal definitions of spatial data types (or algebras) given by Güting [Gü88a, Gü88b], Scholl and Voisard [ScV89, Vo92], and Gargano *et al.* [GaNT91]. All of these proposals do not fulfill most of the criteria given above. In [Gü88a, Gü88b] data types for points, lines, and regions are available but too restricted, e.g. a region is a single simple polygon (without holes). In [ScV89] general regions are defined; in Voisard's thesis [Vo92] this has been extended to general types for points and lines. However, the definitions are unnecessarily complex. In [GaNT91] there is only a single type for all kinds of geometric objects; a value is essentially a set of sets of pixels. We feel this is not sufficient, since many interesting spatial operations cannot be expressed. As mentioned, all of these proposals give formal definitions. However, those of Güting and of Scholl and Voisard are not based on finite resolution; hence the numeric correctness problems are not addressed. Gargano *et al.* base their definitions in principle on a finite underlying set (of pixels). But this is not practical since these finite representations are far too large to be efficiently manageable. The geometric consistency problem is not solved in any of these proposals; there is some weak support in [Gü88a] through an *area* data type, but it is not sufficient. Finally, all three proposals have connected their spatial types to a fixed data model – Güting and Gargano *et al.* to the relational model and Scholl and Voisard to a complex object algebra. Only Scholl and Voisard emphasize a clean interface

---

[3] See the discussion in Section 2 and in [GüS93].

between the spatial algebra and the general object model. We shall extend their work by offering an abstract interface not dependent on any particular data model.

Separating geometric primitives from the remainder of geometric modeling was already proposed by Frank and Kuhn [FrK86]. Because of the conflict between the infinite precision real numbers of Euclidean geometry and the finite precision number systems of computers they suggest to abandon coordinate-based geometry and to only consider the topological structures of point sets underlying spatial values. Their topological data model (later continued in [EgFJ89]) is based on simplicial complexes and has a similar purpose as our concept of realms. Essentially they offer an irregular triangular network partition of the plane as a geometric domain over which spatial objects could be defined. However, the connections are missing to the underlying finite arithmetic as well as to spatial data types based on this model. Also, in our view a triangular partition contains too much information; it is sufficient to keep those points and segments in a geometric domain that are needed for spatial attribute values. Finally, their model is an abstract one whereas we show realms within a database context.

Our description and formal development of *realm-based spatial data types* is given in two papers. In the first paper [GüS93] the lower layers, namely numerically robust geometric primitives, realms and their update operations and a number of realm-based structures (cycles, faces, ...) and primitives have been defined. In this paper spatial data types *points*, *lines*, and *regions* and their operations, that is, the spatial algebra (called *ROSE algebra*), are described and defined formally. Related issues such as modeling partitions of the plane within the type system and an abstract object model interface are addressed. We also show how the ROSE algebra can be integrated with a DBMS data model and query language, using O_2 as an example. In the following section we first provide an informal overview of the complete concept.

2 Overview: Realm-Based Spatial Data Types

A *realm* is a set of points and non-intersecting line segments over a discrete domain, that is, a grid, as shown in Figure 1.

Figure 1: Example of a realm

Values of spatial data types can be composed from the objects present in a realm. Figure 2 shows some values definable over the realm of Figure 1. Our realm-based spatial data types are called *points*, *lines*,
Figure 2: Realm objects defined over the realm of Figure 1

and *regions*, hence A and B represent *regions* values, C is a *lines* value, and D a *points* value. The precise structure of these values is not yet relevant here. One can imagine A and B to belong to two adjacent countries, C to represent a river, and D a city.

The underlying grid of a realm arises simply from the fact that numbers have a finite representation in computer memory. In practice, these representations will be of fixed length and correspond to INTEGER or REAL data types available in programming languages (or to special, higher precision implementations of number systems). Of course, the resolution will be much finer than could be shown in Figure 1.

The concept of a realm as a basis of spatial data types serves the following purposes:
- It enforces *geometric consistency* of related spatial objects. For example, the common part of the borders of countries A and B is exactly the same for both objects.
- It guarantees nice *closure properties* for the computation with spatial data types above the realm. For example, the intersection of region B with line C (the part of river C lying within country B) is also a realm-based *lines* value.
- It shields geometric computation in query processing from numeric correctness and robustness problems. This is because such problems arise essentially from the computation of intersection points of line segments which normally do not lie on the grid. With realm-based SDTs, there are *never any new intersection points computed* in query processing. Instead, the numeric problems are treated *below* the realm level, namely, whenever updates are made to a realm.
- Additionally, a data structure representing a realm can be used as an index into the database. Our implementation concept assumes that each point and segment in a realm has an associated list of logical pointers to the spatial attribute values defined over it in the database.

Let us now focus on the treatment of numerical correctness problems below and within the realm level. This is necessary because geometric data coming from the application are not intersection-free, as required for a realm. Application data can at the lowest level of abstraction be viewed as a set of points and *intersecting* line segments. These need to be transformed into a realm. As mentioned before, the fundamental problem is that intersection points usually do not lie on the grid.
Figure 3

Figure 4

In Figure 3, the intersection point D' of line segments A and B will be moved to the closest grid point D. This leads, for example, to the following topological errors: (1) A test whether D lies *on* A or B fails. (2) A test whether D lies properly within some area defined below A and B will incorrectly yield *true*. (3) If there is another segment C between the true intersection point and D, D will be reported to lie on the wrong side of C. The basic idea to avoid these errors is to slightly change segments A and B by transforming them into chains of segments going through D, as shown in Figure 4. However, this does not suffice, since it allows a segment to drift (through a series of intersections) by an arbitrary distance from its original position. For example, a further intersection of A with some segment C (Figure 5) is resolved as shown in Figure 6, where intersection point E has already a considerable distance from the true intersection point of A and C. Note in particular that segment A has in Figure 6 been moved to the other side of a grid point (indicated by the arrow) which may later be reported to lie on the wrong side of A.

Figure 5

Figure 6

A refined solution was proposed by Greene and Yao [GrY86]. The idea is to define for a segment *s* an *envelope E(s)* roughly as the collection of grid points that are immediately above, below, or on *s*. An intersection of *s* with some other segment may lead to a requirement that *s* should pass through some point *P* on its envelope (the grid point closest to the true intersection point). This requirement is then fulfilled by *redrawing s* by some polygonal line *within the envelope* rather than by simply connecting *P* with the start and end points of *s*. Figure 7 shows a segment *s* (drawn fat) together with the grid points of its envelope. Slightly above *s* a *redrawing* of *s* through *P* is shown.

Intuitively, the process of redrawing can be understood as follows: Think of segment *s* as a rubber band and the points of the envelope as nails on a board. Now grip *s* at the true intersection point and pull it around *P*. The resulting polygonal path is the redrawing. The number of segments of this path is in the worst case logarithmic in the size of the grid, but it seems that in most cases only very few segments are created. This approach guarantees that the polygonal line describing a segment always remains within the envelope of the original segment. We adopt the technique for realms. It then means
Figure 7: Redrawing of a segment *s* through an envelope point *P*

that by redrawing a segment can never drift to the other side of a realm point. It might still happen, though, that after a redrawing a realm point is found to lie *on* a segment which it did not originally.

The formal definition of realm-based SDTs is organized as a series of layers. Each layer defines its own structures and primitives, using the notions of the layers below. These layers are described bottom-up in the companion paper [GüS93] and in the rest of this paper. Let us briefly provide an overview of this development.

The lowest layer introduces *robust geometric primitives*. It defines a discrete space $N \times N$ where $N = \{0, ..., n - 1\}$ is a subset of the natural numbers. The objects in this space are points and line segments with coordinates in N, called *N-points* and *N-segments*. A number of operations (predicates) such as whether an N-point lies *on* an N-segment or whether two N-segments *intersect*, and which N-point is the result of intersecting two N-segments, are defined. The crucial point is that these definitions are given in terms of error-free integer arithmetic, hence they are directly implementable.

Next, geometric *realms* are defined as described above; elements are called *R-points* and *R-segments*. Basic operations on realms are insertion and deletion of N-points and N-segments which may trigger the redrawing of segments as described above. Realms offer an interface to cooperate with a database system. For example, the operation of inserting an N-segment returns besides a modified realm a redrawing of the inserted segment and a set of redrawings of segments in the database that need to be modified together with logical pointers to database representations of these segments.

The second layer defines certain *structures present in a realm* that serve as a basis for the definition of SDTs. A realm can be viewed as a planar graph; an *R-cycle* is a cycle of this graph. An *R-face* is an *R*-cycle possibly enclosing some other disjoint *R*-cycles corresponding to a region with holes. An *R-unit* is a minimal *R*-face. These three notions support the definition of a <u>regions</u> data type. An *R-block* is a connected component of the realm graph; it supports the definition of a <u>lines</u> data type. For all of these structures there are also predicates defined to describe their possible relationships.

This completes the scope of [GüS93]. The definitions of the first two layers needed in this paper are reviewed in Section 3.

The third layer (Section 4) introduces *spatial data types <u>points</u>, <u>lines</u>,* and <u>regions</u> and defines the structure of corresponding values. A <u>points</u> value is a set of R-points. There are two alternative views of <u>lines</u> and <u>regions</u>. The first is that a <u>lines</u> value is a set of R-segments and a <u>regions</u> value a set of R-units. The other view is equivalent but "semantically richer": A <u>lines</u> value is a set of disjoint R-blocks and a <u>regions</u> value a set of (edge-) disjoint R-faces. There are also *spatial algebra primitives* defined on values of these types.

The following two sections prepare the definition of the fourth and final layer. In Section 5 a flexible type system is introduced that allows one to precisely describe polymorphic operations that are central to the ROSE algebra. In this type system it is also possible to cleanly model partitions of the plane so that operations can be constrained to be applicable to partitions or regions of partitions. A *partition* is essentially a set of objects whose _regions_ attribute values are disjoint.

In Section 6 the *object model interface* (*OMI*) is defined. We identify a number of concepts that need to be present in the DBMS data (or object) model to allow it to cooperate with our spatial algebra. The OMI has two parts. The first part is needed to define the semantics of operations of the ROSE algebra, in particular for complex operations that manipulate sets of objects. The second part is needed to embed the ROSE algebra into a query language; it consists of a number of facilities within the query language that are required to make a full use of the ROSE algebra possible. The corresponding idea at the system level is that any extensible database system offering an OMI implementation can cooperate with a *spatial type extension package* (*STEP*) realizing the spatial algebra.

Then as a top layer the *ROSE algebra* is described in Section 7; the semantics of all operations are formally defined. There are four classes of operations:
- spatial predicates expressing topological relationships (e.g. **inside**, **adjacent**)
- operations returning atomic spatial values (e.g. **intersection**, **contour**)
- operations returning numbers (e.g. **length**, **dist**)
- operations on sets of objects (e.g. **overlay**, **fusion**)

The last group of operations manipulates not only SDT values but also the objects they are associated with.

In Section 8 we show how the ROSE algebra can be integrated with a given DBMS data model and query language, choosing O_2 as an example. This illustrates the object model interface. Example queries in O_2SQL/ROSE are also shown to demonstrate the "expressive power" of this spatial algebra.

3 Review: Robust Geometric Primitives, Realms, and Realm-Based Structures

In this section we review the concepts and formal definitions from [GüS93] needed as a basis for defining the ROSE algebra. We have already mentioned that there are several layers of definitions each of which introduces its own structures and operations and uses the notions of the layers below. To be able to distinguish operations of the various layers we use the following typographical convention:
- Layer 1 - robust geometric primitives: underscore (e.g. intersect)
- Layer 2 - realms and realm-based primitives: underscore italic (e.g. _area-disjoint_)
- Layer 3 - spatial algebra primitives: bold italic (e.g. **_area-disjoint_**)
- Layer 4 - ROSE operations: bold (e.g. **inside**)

A summary of the various layers with their objects and operations is given in the Appendix.

3.1   Robust Geometric Primitives

The lowest layer introduces a finite discrete space $N \times N$ with $N = \{0, ..., n-1\} \subseteq \mathbf{N}$, points and line segments over this space, and some simple predicates and operations on them. All definitions are

based on error-free integer arithmetic which enables direct and robust implementation. An *N-point* is a pair $(x, y) \in N \times N$. An *N-segment* is a pair of distinct *N*-points (p, q); the segments (p, q) and (q, p) are defined to be equal. P_N denotes the set of all *N*-points and S_N the set of all *N*-segments. Formal definitions of *robust geometric primitives* defined on *N*-points and *N*-segments are given in [GüS93]. We explain the primitives informally here: Two *N*-segments <u>meet</u> if they have exactly one end point in common. They <u>overlap</u> if they are collinear and share a (partial) *N*-segment. If they have exactly one common point but do not meet, they <u>intersect</u>. They are <u>disjoint</u> if they are neither equal nor <u>meet</u> nor <u>overlap</u> nor <u>intersect</u>. The <u>on</u> primitive tests whether an *N*-point lies on an *N*-segment; the <u>in</u> primitive does nearly the same but the *N*-point must not coincide with one of the end points of the *N*-segment. The <u>intersection</u> primitive calculates the intersection point of two *N*-segments and rounds it to the nearest *N*-point.

3.2   Realms

Realms serve as a basis for SDTs and essentially represent a finite, user-defined set of points and *non-intersecting* line segments over a discrete domain. Given *N*, a *realm over N*, or *N-realm* for short, is a set $R = P \cup S$ such that

(i) $P \subseteq P_N, S \subseteq S_N$

(ii) $\forall s \in S : s = (p, q) \Rightarrow p \in P \wedge q \in P$

(iii) $\forall p \in P \; \forall s \in S : \neg (p \underline{\text{ in }} s)$

(iv) $\forall s, t \in S, s \neq t : \neg (s \text{ and } t \underline{\text{ intersect}}) \wedge \neg (s \text{ and } t \underline{\text{ overlap}})$

The elements of *P* and *S* are called *R-points* and *R-segments*. There is an obvious interpretation of a realm as a spatially embedded planar graph with set of nodes *P* and set of edges *S*.

3.3   Realm-Based Structures and Primitives

This layer defines certain structures and relationships between these structures that can be discovered within a realm and that are useful for the definition of SDTs. A realm can be viewed as a planar graph; informally, an *R-cycle* is a cycle of this graph. An *R-face* is an *R*-cycle possibly enclosing some other disjoint *R*-cycles corresponding to a region with holes. An *R-unit* is a minimal *R*-face. These three notions support the definition of a <u>regions</u> data type. An *R-block* is a connected component of the realm graph; it supports the definition of a <u>lines</u> data type. For all of these *realm-based structures* predicates (primitives) are defined to describe their possible relationships. We now review the most important formal definitions.

An *R-cycle c* is just a cycle in the graph interpretation of a realm, defined by a set of *R*-segments $S(c) = \{s_0, ..., s_{m-1}\}$, such that

(i) $\forall i \in \{0, ..., m\text{-}1\} : s_i \underline{\text{ meets }} s_{(i+1) \bmod m}$

(ii)   No other pairs of segments in $S(c)$ <u>meet</u>.

Obviously the following relationships may exist between an *N*-point *p* and an *R*-cycle *c*:

(i) $p \underline{\text{ on }} c \quad :\Leftrightarrow \quad \exists s \in S(c) : p \underline{\text{ on }} s$
Figure 8: Possible relationships between two R-cycles

For $p = (x, y)$ let $s_p = ((x, y), (x, n - 1))$ (that is, a vertical segment extending from p upwards to the edge of the grid). Let $S_r(c)$ be the set of segments in $S(c)$ whose right end point, but not the left one, is <u>on</u> s_p (the left end point is the smaller one of the two end points in the (x, y)-lexicographical order). Let $S_i(c)$ be the segments in $S(c)$ that <u>intersect</u> s_p. Then

(ii) p <u>in</u> c $:\Leftrightarrow$ $\neg\, p$ <u>on</u> $c \wedge |S_r(c)| + |S_i(c)|$ is odd

(iii) p <u>out</u> c $:\Leftrightarrow$ $\neg\, (p$ <u>on</u> $c \vee p$ <u>in</u> $c)$

Hence c partitions the set P_N into three subsets $P_{in}(c)$, $P_{on}(c)$, and $P_{out}(c)$. Let $P(c) := P_{on}(c) \cup P_{in}(c)$.

Cycles are interesting because they are the basic entities for the definition of regions over realms. The relationships shown in Figure 8 may be distinguished between two R-cycles c_1 and c_2. The following terminology is introduced for these configurations:

c_2 is
- (*area-*)*inside* (i, ii, iii)
- *edge-inside* (ii, iii)
- *vertex-inside* (iii)

c_1 and c_2 are
- *area-disjoint* (iv, v, vi)
- *edge-disjoint* (v, vi)
- (*vertex-*)*disjoint* (vi)

c_1.

The meaning is that (i) c_2 is (w.r.t. *area*) *inside* c_1, (ii) additionally has no common edges with c_1, (iii) has not even common vertices with c_1. Similarly (iv) c_2 is *disjoint* w.r.t. *area* with c_1, (v) additionally has no common edges with c_1, (vi) additionally has not even common vertices with c_1. *area-inside* is the standard interpretation of the term *inside*, *vertex-disjoint* the standard interpretation of the term *disjoint*. Furthermore there are two positive notions: c_1 and c_2 are *adjacent* if they are area-disjoint and have common edges, they *meet* if they are edge-disjoint and have common vertices. The predicates are formally defined as follows:

c_1 (<u>*area-*</u>)<u>*inside*</u> c_2	$:\Leftrightarrow$ $P(c_1) \subseteq P(c_2)$
c_1 <u>*edge-inside*</u> c_2	$:\Leftrightarrow$ c_1 <u>*area-inside*</u> $c_2 \wedge S(c_1) \cap S(c_2) = \varnothing$
c_1 <u>*vertex-inside*</u> c_2	$:\Leftrightarrow$ c_1 <u>*edge-inside*</u> $c_2 \wedge P_{on}(c_1) \cap P_{on}(c_2) = \varnothing$
c_1 and c_2 are <u>*area-disjoint*</u>	$:\Leftrightarrow$ $P_{in}(c_1) \cap P(c_2) = \varnothing \wedge P_{in}(c_2) \cap P(c_1) = \varnothing$
c_1 and c_2 are <u>*edge-disjoint*</u>	$:\Leftrightarrow$ c_1 and c_2 are <u>*area-disjoint*</u> $\wedge S(c_1) \cap S(c_2) = \varnothing$
c_1 and c_2 are (<u>*vertex-*</u>)<u>*disjoint*</u>	$:\Leftrightarrow$ c_1 and c_2 are <u>*edge-disjoint*</u> $\wedge P_{on}(c_1) \cap P_{on}(c_2) = \varnothing$
c_1 and c_2 are <u>*adjacent*</u>	$:\Leftrightarrow$ c_1 and c_2 are <u>*area-disjoint*</u> $\wedge S(c_1) \cap S(c_2) \neq \varnothing$

$$c_1 \text{ and } c_2 \text{ } \underline{meet} \qquad\qquad :\Leftrightarrow \text{ } c_1 \text{ and } c_2 \text{ are } \underline{edge\text{-}disjoint} \wedge P_{on}(c_1) \cap P_{on}(c_2) \neq \emptyset$$

One can observe similar ways how an R-segment s can lie within an R-cycle c:

- s (*area*-)*inside* c (i, ii, iii)
- s *edge-inside* c (ii, iii)
- s *vertex-inside* c (iii)

Figure 9: Possible relationships of an R-segment lying within an R-cycle

For an R-point p and an R-cycle c we have two possibilities:

- p (*area*-)*inside* c (i, ii)
- p *vertex-inside* c (ii)

Figure 10: Possible relationships of an R-point lying within an R-cycle

Formal definitions are left to the reader. Based on the concept of R-cycles, for the definition of a SDT for regions the notions *R-face* and *R-unit* are introduced which describe regions from two different perspectives and which are used equivalently. Both of them essentially define polygonal regions with holes. An R-unit is a "minimal" R-face in the sense that any R-face within the R-unit is equal to the R-unit. Hence R-units are the smallest region entities that exist over a realm. In the next section a region (data type) will be defined that can either be viewed as a set of R-faces or, equivalently, as a set of R-units. The first view emphasizes a minimal representation of the boundary of a region whereas the latter view supports the definition of set operations for regions.

An *R-face f* is a pair (c, H) where c is an R-cycle and $H = \{h_1, ..., h_m\}$ is a (possibly empty) set of R-cycles such that the following conditions hold (let $S(f)$ denote the set of segments of all cycles of f):

(i) $\forall i \in \{1, ..., m\} : h_i$ *edge-inside* c

(ii) $\forall i, j \in \{1, ..., m\}, i \neq j : h_i$ and h_j are *edge-disjoint*

(iii)   Each cycle in $S(f)$ is either equal to c or to one of the cycles in H (no other cycle can be formed from the segments of f)

The first two conditions allow a hole within a face to touch in a vertex the boundary cycle c or another hole. This is necessary in order to achieve closure under operations (e.g. subtracting face g from face f may lead to a hole in f). On the other hand, to allow two holes to be area-disjoint makes no sense, since then adjacent holes could be merged by eliminating common boundary segments (similarly for adjacency of a hole with the boundary). The last condition ensures uniqueness of representation, that is, there are no two different interpretations of a set of segments as sets of faces. Note that in a given set of faces it is entirely possible for a hole of one face to contain some other faces ("islands").

The grid points belonging to an R-face f are defined as $P(f) := P(c) \setminus \bigcup_{i=1}^{m} P_{in}(h_i)$.

The possible relationships between an R-point p or an R-segment s and an R-face $f = (c, H)$ are:

(i) p (*area-*)*inside* f :$\Leftrightarrow$ p *area-inside* $c \wedge \forall\, h \in H : \neg\, p$ *vertex-inside* h

(ii) s (*area-*)*inside* f :$\Leftrightarrow$ s *area-inside* $c \wedge \forall\, h \in H : \neg\, s$ *edge-inside* h

The various notions of *inside* and *disjoint* can be extended for the comparison of two R-faces $f = (f_0, \overline{F})$ and $g = (g_0, \overline{G})$, for example:

  f (*area-*)*inside* g :$\Leftrightarrow$ f_0 *area-inside* $g_0 \wedge \forall\, \bar{g} \in \overline{G} : \bar{g}$ *area-disjoint* $f_0 \vee \exists\, \hat{f} \in \overline{F} : \bar{g}$ *area-inside* $\hat{f}$

This definition is illustrated in Figure 11.
Figure 11: Example of the relationship f *area-inside* g

  f *area-disjoint* g :$\Leftrightarrow$ f_0 *area-disjoint* $g_0 \vee \exists\, \bar{g} \in \overline{G} : f_0$ *area-inside* $\bar{g} \vee \exists\, \hat{f} \in \overline{F} : g_0$ *area-inside* $\hat{f}$

  f *edge-disjoint* g :$\Leftrightarrow$ f_0 *edge-disjoint* $g_0 \vee \exists\, \bar{g} \in \overline{G} : f_0$ *edge-inside* $\bar{g} \vee \exists\, \hat{f} \in \overline{F} : g_0$ *edge-inside* $\hat{f}$

The meaning of the remaining predicates *edge-inside*, *vertex-inside*, *vertex-disjoint*, *adjacent*, *meet* should be clear; definitions are omitted for brevity. We add a primitive *encloses*:

  f *encloses* g :$\Leftrightarrow$ $\exists\, \hat{f} \in \overline{F} : g_0$ *area-inside* $\hat{f}$

An R-unit as a minimal R-face is defined as follows. Let $F(R)$ denote the set of all possible R-faces. Let f be an R-face.

  f is an R-*unit* :$\Leftrightarrow$ $\forall\, g \in F(R) : g$ *area-inside* $f \Rightarrow g = f$

We denote by $U(R)$ the set of all R-units. Figure 12 shows an example of a realm with all its R-units u_i and an emphasized R-face which is not an R-unit.

In [GüS93] the equivalence of two representations of a region over a realm is formally established, namely, as a set of (pairwise) edge-disjoint R-faces, and as a set of area-disjoint R-units. Operations called *faces* and *units* are defined to convert between the two formal representations. Hence the equivalence can be expressed as: $\forall\, F \subseteq F(R)$: *faces*(*units*($F$)) = F. The operation *units* is defined as *units*(F) := $\{u \in U(R)\,|\,\exists\, f \in F\colon u$ *area-inside* $f\}$. The operation *faces* basically works as follows: From a given set of area-disjoint R-units, its multiset of boundary segments is formed. Then, all segments occurring twice are removed. The remaining set of segments defines uniquely a set of edge-disjoint R-faces. - As a result, we can now freely convert between the two formal representations and use in the definition of operations always the more convenient one.
Figure 12: Example of an *R*-face which is not an *R*-unit

Let T be a set of *R*-segments, that is, $T \subseteq S$. Then *cycles*(T) denotes the set of all cycles (in the graph interpretation of realm *R*) that can be formed from segments in T. Furthermore, we say that a set T of *R*-segments *describes a set of pairwise edge-disjoint R-faces* :⇔ there exists a set of edge-disjoint *R*-faces F such that $T = S(F)$. If T describes a set of edge-disjoint *R*-faces, then a function *regions*(T) is defined to return this set of faces.

For the definition of an SDT for lines the notion of an *R-block* is introduced. A set T of *R*-segments is called *connected* :⇔ $\forall\ r, t \in T\ \exists\ s_1, ..., s_m \in T : r = s_1, t = s_m$, and $\forall\ i \in \{1, ..., m - 1\} : s_i$ and s_{i+1} <u>meet</u>. An *R-block* b is a connected subgraph in the graph interpretation of a realm, defined by its set of *R*-segments $S(b)$. Two *R*-blocks b_1 and b_2 are <u>*disjoint*</u> :⇔ $\forall\ s_1 \in S(b_1)\ \forall\ s_2 \in S(b_2) : s_1$ and s_2 are <u>disjoint</u>. For an *R*-point p we consider the angularly sorted cyclic list L_p of *R*-segments $s \in S(b_1) \cup S(b_2)$ that meet in p. p is called a *meeting point* if L_p is the concatenation of two sublists $L_{p,1}$ and $L_{p,2}$ so that all *R*-segments of $L_{p,1}$ are elements of $S(b_1)$ and all *R*-segments of $L_{p,2}$ are elements of $S(b_2)$, or vice versa (see Figure 13).

Let b_1 and b_2 be two *R*-blocks.

b_1 and b_2 <u>*meet*</u>	:⇔	$\exists\ s \in S(b_1)\ \exists\ t \in S(b_2)$: s and t <u>meet</u> in a meeting point $\wedge$
		$\forall\ s \in S(b_1)\ \forall\ t \in S(b_2) : s \neq t\ \wedge$
		(s and t <u>meet</u> in $p \Rightarrow p$ is a meeting point)
b_1 and b_2 <u>*intersect*</u>	:⇔	$\forall\ s \in S(b_1)\ \forall\ t \in S(b_2) : s \neq t\ \wedge \exists\ s \in S(b_1)\ \exists\ t \in S(b_2) : s$ and t <u>meet</u>
		in $p \wedge p$ is not a meeting point

Again, we have two equivalent representations of a <u>*lines*</u> value, namely, as a set of segments, or as a set of disjoint *R*-blocks. For a set of segments $T \subseteq S$, *blocks*(T) denotes its partition into maximal connected components. Then $S(blocks(T)) = T$.

Some primitives relate an *R*-block b and an *R*-face f.

b (<u>*area-*</u>)*inside* f	:⇔	$\forall\ s \in S(b) : s$ <u>*area-inside*</u> f
b and f <u>*meet*</u>	:⇔	$\forall\ s \in S(b) : \neg\ s$ <u>*area-inside*</u> $f \wedge \exists\ s \in S(b)\ \exists\ t \in S(f) : s$ and t <u>meet</u>

Figure 13: p is a meeting point, p' is not a meeting point.

$$b \text{ and } f \underline{\textit{intersect}} \quad :\Leftrightarrow \quad \exists\, s \in S(b) : s \underline{\textit{area-inside}} f$$

Embedding N-points in the Euclidean plane, we can define the distance $\underline{\textit{dist}}(p, q)$ between two N-points, the length $\underline{\textit{length}}(s)$ of an N-segment, and the area $\underline{\textit{area}}(c)$ inside an R-cycle in the well-known way. The area inside an R-face $f = (c, H)$ is defined as $\underline{\textit{area}}(f) := \underline{\textit{area}}(c) - \sum_{h \in H} \underline{\textit{area}}(h)$.

4 Realm-Based Spatial Data Types

The realm-based structures reviewed in the previous section form the basis for a definition of spatial data types. The basic types introduced are called $\underline{\textit{points}}$, $\underline{\textit{lines}}$, and $\underline{\textit{regions}}$[4] and will be part of a spatial algebra defined in Section 7. There is a "flat" and a "structured" view of values of these types. The "flat" view is the following:

> *For a given realm R, a value of type $\underline{\textit{points}}$ is a set of R-points, a value of type $\underline{\textit{lines}}$ is a set of R-segments, and a value of type $\underline{\textit{regions}}$ is a set of R-units.*

The "structured" view, that we shall assume as the formal definition, is as follows:

> *For a given realm R, a value of type $\underline{\textit{points}}$ is a set of R-points, a value of type $\underline{\textit{lines}}$ is a set of pairwise disjoint R-blocks, and a $\underline{\textit{regions}}$ value is a set of pairwise edge-disjoint R-faces.*

We have shown in [GüS93] that the two views are equivalent. The first view is conceptually very simple and supports a direct understanding of set operations. The second view is "semantically richer" and shows $\underline{\textit{lines}}$ and $\underline{\textit{regions}}$ values as consisting of a number of   components (blocks or faces). Moreover, it allows one to express relationships between these components and also emphasizes the representation of the boundary in case of regions. Note that a $\underline{\textit{regions}}$ value may have holes. Holes are important because (i) they allow for an adequate modelling of area features, and (ii) they make it possible to obtain closure under point set operations. Figure 14 illustrates the data types.

It should be obvious that these data types have very nice closure properties. They are closed under the geometric operations *union*, *intersection*, and *difference* with regard to the same realm. That is, the result of such an operation is a realm-based value as well and corresponds to the definitions of the spatial data types given above. The geometric operations can be reduced to the corresponding set-theoretic ones and are defined as follows. Let P_1, P_2 be two $\underline{\textit{points}}$ values, L_1, L_2 two $\underline{\textit{lines}}$ values, and R_1, R_2 two $\underline{\textit{regions}}$ values. Then

---

[4] Unfortunately, there is a collision between the typographical conventions for realm-based primitives and for data types (both underscore italic). It cannot be avoided in order to remain consistent with [GüS93] and [Gü93] (the latter will be used below as a framework for defining signatures).
a *points* value a *lines* value a *regions* value

Figure 14: Examples of spatial values

union $(P_1, P_2) := P_1 \cup P_2$

union $(L_1, L_2) := blocks(S(L_1) \cup S(L_2))$

union $(R_1, R_2) := faces(units(R_1) \cup units(R_2))$

For **intersection** and **difference** the definitions are analogous. Due to the underlying realms, these operations both in theory *and* in practice obey the usual algebraic laws (commutativity, associativity, distributivity, ...).

The realm-based primitives reviewed in the previous section offer a formal basis for the definition of *spatial algebra primitives* of which **union**, **intersection**, and **difference** have just been introduced. The following further primitives are needed. Let F and G be two *regions* values.

F and G are **area-disjoint**	$:\Leftrightarrow$	$\forall f \in F \ \forall g \in G : f$ and g are *area-disjoint*
F and G are **adjacent**	$:\Leftrightarrow$	F and G are **area-disjoint** $\land \exists f \in F \ \exists g \in G : f$ and g are *adjacent*

The meaning of the remaining predicates (**area-**)**inside**, **edge-inside**, **vertex-inside**, **edge-disjoint**, (**vertex-**)**disjoint**, **meet** should be clear; definitions are omitted for brevity. We define two further predicates **intersect** and **encloses**:

F and G **intersect**	$:\Leftrightarrow$	$(units(F) \cap units(G) \neq \varnothing)$
F **encloses** G	$:\Leftrightarrow$	$\forall g \in G \ \exists f \in F : f \ encloses \ g$

Let P and Q be two *points* values.

P and Q are **disjoint**	$:\Leftrightarrow$	$P \cap Q = \varnothing$

Let K and L be two *lines* values.

K and L are **disjoint**	$:\Leftrightarrow$	$\forall k \in K \ \forall l \in L : k$ and l are *disjoint*
K and L **meet**	$:\Leftrightarrow$	$(\forall k \in K \ \forall l \in L : k$ and l are *disjoint* $\lor k$ and l *meet*) $\land$ $(\exists k \in K \ \exists l \in L : k$ and l *meet*)
K and L **intersect**	$:\Leftrightarrow$	$(\forall k \in K \ \forall l \in L : k$ and l are *disjoint* $\lor k$ and l *intersect*) $\land$ $(\exists k \in K \ \exists l \in L : k$ and l *intersect*)

Let P be a *points* value, L a *lines* value, F a *regions* value, and v, w *lines* or *regions* values.

P (**area-**)**inside** F	$:\Leftrightarrow$	$\forall p \in P \ \exists f \in F : p \ area\text{-}inside \ f$

L **(area-)inside** F	$:\Leftrightarrow$	$\forall\, l \in L\, \exists f \in F : l\ \underline{area\text{-}inside}\, f$
L and F **meet**	$:\Leftrightarrow$	$\forall\, l \in L\, \forall f \in F : \neg\, l\ \underline{area\text{-}inside}\, f\ \wedge$
		$\exists\, l \in L\, \exists f \in F : l$ and $f\ \underline{meet}$
L and F **intersect**	$:\Leftrightarrow$	$\exists\, l \in L\, \exists f \in F : l$ and $f\ \underline{intersect}$
P **on_border_of** v	$:\Leftrightarrow$	$\forall\, p \in P\, \exists\, s = (q_1, q_2) \in S(v) : p = q_1 \vee p = q_2$
v **border_in_common** w	$:\Leftrightarrow$	$\exists\, s \in S(v)\, \exists\, t \in S(w) : s = t$

5 The Type System

The ROSE algebra that we are going to define is a system of spatial data types together with operations between these types. Many of the operations are applicable to several types. Hence we need a framework and notations to describe polymorphic operations. We would also like to express certain constraints for the applicability of some operations. For example, an adjacency test operation for regions should only be allowed if the two operands are known to come from a set of disjoint regions (that is, a *partition* of the plane). Similarly, an overlay operation should be constrained to two partition operands and not be applicable to arbitrary collections of objects with region attributes. In this section we briefly review a type system powerful enough to express polymorphic operations and the mentioned constraints in a precise manner.

5.1   Second-Order Signature

A system of several sets and functions between these sets is called a *many-sorted algebra*. A *many-sorted signature* describes the syntactic aspect of a many-sorted algebra. It consists of two sets of symbols called *sorts* and *operators*; operators are annotated with strings of sorts. Each sort is the *name of a set* of the algebra and each operator the *name of a function*. For example, the symbols <u>lines</u>, <u>regions</u>, and <u>bool</u> may be sorts and **intersects**_{<u>lines regions bool</u>} an operator. The annotation with sorts defines the functionality of the operator. A signature defines a set of terms.

Second-order signature, introduced in [Gü93], is a system of two coupled many-sorted signatures where the top-level signature offers *kinds* (sets of types) as sorts and *type constructors* as operators. The terms of this signature define a collection of types, that is, a type system. A simple example is shown below. Each line describes a group of operators (type constructors in this case) with the same functionality.

kinds DATA, GEO, SET

type constructors

	$\rightarrow$ DATA	<u>int</u>, <u>real</u>, <u>bool</u>
	$\rightarrow$ GEO	<u>points</u>, <u>lines</u>, <u>regions</u>
GEO	$\rightarrow$ SET	<u>set</u>

Here <u>int</u>, <u>set</u>, etc. are type constructors which generally have one or more argument kinds and one result kind. A type constructor with zero argument kinds is called a *constant type*. In the example all constructors except for <u>set</u> are constant types. The terms of this signature, and therefore the available

types of this type system, can be classified by result kinds. For example, there are exactly three types of kind GEO. The types of kind SET are $\underline{set}(\underline{points})$, $\underline{set}(\underline{lines})$, and $\underline{set}(\underline{regions})$. In this example the set of types is finite, but this is generally not the case.

A second, bottom-level, signature uses the types defined by the top-level signature as sorts. Usually one does not write the bottom-level signature directly but rather a *signature specification* which allows one to quantify over kinds and so to define polymorphic operations. For example, we can define:

$$\forall\ data\ \text{in DATA.} \qquad data \times data \qquad \rightarrow \underline{bool} \qquad =, <, \leq, \geq, >$$

$$\forall\ geo\ \text{in GEO.} \qquad geo \times \underline{regions} \qquad \rightarrow \underline{bool} \qquad \textbf{inside}$$

Here *data* and *geo* are *type variables* ranging over the kinds DATA and GEO, respectively. The semantics of such a signature specification is a many-sorted signature which is obtained by substituting for each type variable all types in the respective kind. Hence the first specification says that the comparison operators are defined for two integers, two reals, or two boolean values. The second specification defines an **inside** operator with functionalities $\underline{points} \times \underline{regions} \rightarrow \underline{bool}$, $\underline{lines} \times \underline{regions} \rightarrow \underline{bool}$, and $\underline{regions} \times \underline{regions} \rightarrow \underline{bool}$.

This completes already the description of the basic scheme of second-order signature. Of course, there are also other ways of specifying polymorphic operations; for a discussion and references see [Gü93].

The basic scheme has been extended in [Gü93] to support the definition of flexible database query languages. Some of these techniques are needed in this paper:

Extensions of the concept of signature. The purpose is to include for a given collection of types (sorts, to be precise) "automatically" product types, union types, list types, and function types. If $s, s_1, ..., s_n$ and t are sorts then

- $(s_1 \times ... \times s_n)$ is a sort (the product sort, denoting tuples of instances of the s_i)
- $(s_1 \cup ... \cup s_n)$ is a sort (the union sort, denoting instances in any of the s_i)
- s^+ is a sort (the sort denoting non-empty lists of instances of s)
- $(s_1 \times ... \times s_n \rightarrow t)$ is a sort (denoting functions from $s_1 \times ... \times s_n$ into t).

With these extensions one can, for example, define the following operations:

$$\forall\ geo\ \text{in GEO.}$$

$$(\underline{set}(geo))^+ \qquad\qquad \rightarrow \underline{set}(geo) \qquad \textbf{union}$$

$$\underline{set}(geo) \times (geo \rightarrow \underline{bool}) \qquad \rightarrow \underline{set}(geo) \qquad \textbf{select}$$

Here the **union** operator takes one or more operands that are all sets of geometric values of the same type and returns a set (the union) of this type. The **select** operator takes an operand of type $\underline{set}(geo)$ and a predicate on type *geo* and returns a subset of the operand set fulfilling the predicate.

Specification techniques. Two additional specification techniques are illustrated by the following example:

$$\forall\ geo_i\ \text{in GEO.} \qquad (\underline{set}(geo_i))^+ \qquad \rightarrow data: \text{DATA} \quad \textbf{weight}$$

The notation geo_i is related to operators with a variable number of operands and means that for each substitution of the variable geo_i an instance of the kind GEO is selected independently. Hence one

possible operand combination for **weight** would be _set_(_points_) × _set_(_lines_) × _set_(_lines_). With the quantification "∀ _geo_ in GEO" all operands would have to be of the same type (e.g. _set_(_points_)).

The notation "_data_: DATA" is to be read as "some type _data_ in DATA" and means that there is a type mapping associated with the **weight** operator. Intuitively the idea is that the operator determines itself the result type within the kind DATA, depending on the given operand types. This is sometimes useful when it is not possible or desirable to describe the result type precisely in the signature. To define the semantics of such an operator one needs to supply a type mapping function (as a part of a second-order algebra, see [Gü93] for details). In this example, the **weight** operator might return a value of type _int_ if all operands are sets of points (and return the total number of points), and a value of type _real_ otherwise (say, the total area or length). Some examples of meaningful operators with type mappings occur in the ROSE algebra defined below.

Dynamic kinds. (This extension has not yet been covered in [Gü93]). Sometimes it is necessary to modify dynamically the set of instances of a kind, that is, to create new types. For a kind K, the notation _new_(K) creates a new (anonymous) type in K; the value of _new_(K) is a type that can be used in type expressions.

5.2   The Type of a Partition

The term _partition_ is used to refer to a disjoint subdivision of the plane into regions with associated (non-spatial) attributes. For partitions, one would like to define special operations like testing for adjacency (of two regions of a partition) or overlay (of two partitions, resulting in a new partition). The question is how partitions can be described in a type system so that the operations can be constrained to partition operands.

We feel that a partition should be modeled as a set of objects with associated _regions_ attribute values and an additional constraint that for any pair of objects in one particular partition, their _regions_ values are disjoint. To say this in a more general way, we would like to model and manipulate sets of values such that for any two distinct values in such a set a certain condition holds. To consider an example different from partitions, let us assume we would like to model sets of integers with the property that there are no two consecutive integers in the set.

The idea to make this possible in the type system is to introduce _restriction types_ and to collect them within a _special kind_. Let d be a data type and p be a binary predicate on d. Then d^p denotes a kind; each type d' in d^p describes a set of values of type d such that for any two distinct elements of d' the predicate p holds. Furthermore, any such type d' is defined to be a _subtype_ of d which means that all operations defined for type d are also applicable to instances of type d'.

For the "non-consecutive integer" example, we could introduce a predicate "two-apart" on integers, being true if the difference of the two operands is at least two. Then $\underline{int}^{\text{two-apart}}$ denotes a kind whose element types have carrier sets[5] with the desired property. Hence the set {3, 5, 10} would have a type within this kind whereas for the set {1, 2, 3} there would not exist a type within kind $\underline{int}^{\text{two-apart}}$. The types themselves are anonymous (i.e. no explicit names for them need to be introduced).

---

[5] For a type, its set of instances is called the _carrier_.

We use this as follows: The kind $\underline{regions}^{\ area\text{-}disjoint}$ contains all types whose carriers are sets of $\underline{regions}$ values such that any two distinct values of the type are **area-disjoint**. A quantification "$\forall$ *area* in $\underline{regions}^{\ area\text{-}disjoint}$" binds the *area* type variable to any such type. Hence an adjacency test can be defined as:

$$\forall \ area \ \text{in} \ \underline{regions}^{\ area\text{-}disjoint}. \qquad area \times area \rightarrow \underline{bool} \qquad \textbf{adjacent}$$

Here the quantification selects first one particular partition of the plane as a type *area*. Hence it is guaranteed that any two arguments for the operator **adjacent** are from the same partition and are either area-disjoint or equal. Note that when a new partition is created in query processing, we can obtain a corresponding new anonymous type for it with the notation $new(\underline{regions}^{\ area\text{-}disjoint})$.

On the side of the database system this should be supported by making it possible to define restriction types and to use them as attribute domains. For example, assume an operation `area_disjoint` applicable to values of type `regions` has been made known to the DBMS. One might write:

```
type mycountries = restrict (regions, area_disjoint);
class states (name: string; region: mycountries; pop: integer)
```

An insertion of a new object into class `states` should then at least conceptually be viewed as preceded by an insertion of a new `regions` value into the extension of type `mycountries`. It should be checked that the new value is `area_disjoint` with all values already present.

6 The Object Model Interface

Spatial data types as such are rather useless; they need to be integrated into a DBMS data model and query language. On the other hand, the definition of SDTs should be valid regardless of any particular data model and therefore not depend on it. Consequently, SDTs should not be firmly embedded into a particular DBMS data model. Instead, the SDT definition should be based on an abstract interface to the DBMS data model which we call the *object model interface* (*OMI*). Different DBMS data models can then use the spatial algebra as a provided resource for dealing with geometry. In this section we define an object model interface for the ROSE algebra. In fact, there are two aspects of the interface: (1) There are basic concepts and operations in the object model that are needed to *define* the ROSE algebra, and (2) there are constructs and notations needed to embed the ROSE algebra into the query language, that is, to *use* the ROSE algebra.

6.1   Object Model Interface Concepts for Defining the ROSE Algebra

The concepts that are needed to define the ROSE algebra are the following:

- object types/classes
- collections of objects
- functions for accessing (attribute) values from objects
- data types $\underline{int}$, $\underline{real}$, $\underline{bool}$
- a pool of names (for new objects/functions)
- an object aggregation function
- an object extension function

Object types/classes. We assume that each DBMS data model has some notion of one or more object types or classes. For example, in a relational system, this would be relations; in an object-oriented system we may have object class hierarchies, and objects may have a complex structure. In terms of our type system we model this by a kind OBJ; each DBMS object class is represented as a type *obj* in OBJ.

Collections of objects. The structures manipulated in (and obtained as a result of) queries may be sets of tuples, nested relations, sequences of object identifiers, graphs, etc. The most simple, universally valid and data model-independent abstraction is that of a *set of objects*. If a set of objects is not directly available, the DBMS data model must provide functions to transform its structures containing objects into a set of objects, and vice versa. In the type system we have a type constructor *set* applicable to object types.

Functions for accessing attribute values. The OMI views an object as an abstract entity whose internal structure is hidden. It is assumed that objects may have associated values of standard or spatial data types and that these values can be accessed by means of *attribute functions* of type $obj \rightarrow data$, for any type *obj* in OBJ and data type *data*.

Data types int, real, bool. We assume that standard data types for integers, real numbers, and boolean values exist. Some ROSE operations yield results of these types.

A pool of names. Some operations require (new) names as parameters, in particular for introducing derived attributes (attribute functions). We introduce this pool of names as a type *ident* in a kind IDENT.

Object aggregation function. Some spatial operations construct new objects as "aggregation objects". For that purpose the DBMS data model has to provide a "$\otimes$" (product) function which for two objects o_1 of type obj_1 and o_2 of type obj_2 forms an aggregation object $o_1 \otimes o_2$. The same symbol is used to denote a corresponding type mapping operation; hence there is also a product type $obj_1 \otimes obj_2$ and object $o_1 \otimes o_2$ is of type $obj_1 \otimes obj_2$. On the product type all attribute functions defined on either obj_1 or obj_2 are valid; this should be expressed by the type mapping (defined within the object model). In a relational setting, this corresponds to concatenating two tuples when forming a join; the result tuple has the attributes of both operand tuples.

Object extension function. Sometimes it is necessary to add an attribute to objects of a given object type. For that purpose the DBMS data model must offer an extension function denoted by "$\oplus$". At the instance level, this operation adds a data type value to an object, hence $o \oplus v$ is an object o extended by a value v. At the type level, the given object type *obj* is extended by a attribute function *attr* mapping objects into values of some data type *data*. Hence $obj \oplus (attr, data)$ denotes such an extension type of which $o \oplus v$ is an instance if o has type *obj* and v has type *data*.

6.2   Concepts for Embedding the ROSE Algebra into a DBMS Query Language

This part of the object model interface contains requirements about certain notations and constructs needed in the DBMS query language to allow an embedding and a full use of the ROSE algebra. Facilities are needed to

- denote a (spatial) data type value
- denote a collection of objects together with an attribute (attribute function)
- extend objects by derived (attribute) values
- allow naming of an SDT value or a new attribute
- offer a grouping operation.

To motivate why these facilities are needed we give a brief preview of some operations of the ROSE algebra:

$\forall$ *obj* in OBJ. $\forall$ *geo*, *geo$_1$*, *geo$_2$* in GEO.

geo $\times$ *regions*	$\rightarrow$ *bool*	**inside**
lines $\times$ *lines*	$\rightarrow$ *points*	**intersection**
set(*obj*) $\times$ (*obj* $\rightarrow$ *geo$_1$*) $\times$ *geo$_2$*	$\rightarrow$ *set*(*obj*)	**closest**
set(*obj*) $\times$ (*obj* $\rightarrow$ *geo*) $\times$ *ident*	$\rightarrow$ *set*(*o*: OBJ)	**decompose**

The meaning of the first two operations should be obvious. The **closest** operator takes a collection of objects together with a spatial attribute function and a further SDT value v and returns those objects whose attribute value is closest to v (usually one object). The **decompose** operator also takes a collection of objects with a spatial attribute. It produces a new collection of objects as follows: For each object in the operand set its attribute value is decomposed into its components (a component is a point, a block, or a face). If there are n components, then n copies of the original object are produced each of which has one component as the value of a new attribute. The name of the new attribute is supplied as the third parameter of type *ident*.

We now discuss each of the mentioned facilities in turn and illustrate them in the context of the relational model by (a) showing corresponding notations from geo-relational algebra [Gü88] and (b) by extensions that might be used for SQL. In examples, relations

cities (cname: *string*; center: *points*; pop: *int*)
states (sname: *string*; territory: *regions*; language: *string*)

are used.

Denote a data type value. This is needed to supply operands to operations like **inside** or **intersection**. There are two cases: (i) within the scope of an "object set iteration", and (ii) without object set iteration. In the first case, each object in a set is considered in turn and it suffices to write down the name of an attribute to denote a single data type value.

Q1: Calculate the population (in thousands) of all cities in Germany.

- (a) cities **select**[center **inside** Germany] **extend**[pop/1000 {thousands}]
- (b) **select** cname, thousands: pop/1000
  from cities
  where center **inside** Germany

Here within the scope of a **select** or **extend** operator of geo-relational algebra or within the where-clause or select-clause of SQL we have an "object set iteration" and an attribute name denotes a data type value.

In the second case (without object set iteration), one would like to refer to a single data type value, in particular, to the attribute value of some specific object. A notation is needed to identify a single object

and to access one of its attributes. In the geo-relational algebra this is done by an **extract** operator. An error message should appear if none or more than one object is identified by the condition.

Q2: Provide the geometry of the city Hagen (assuming there is only one "Hagen" in the cities relation).

  (a) cities **extract**[cname = "Hagen"; center] {Hagen}

  (b) **let** Hagen
      extract center
      from cities
      where cname = "Hagen"

Here we have extracted a single *points* value from the cities relation. We have also assigned a name (Hagen) to this value so that it can be used in later queries.

Denote a collection of objects together with an attribute. This is needed for operations like **closest** or **decompose**. Recall the signature for **closest**:

$$\underline{set}(obj) \times (obj \rightarrow geo_1) \times geo_2 \qquad \rightarrow \underline{set}(obj) \qquad \textbf{closest}$$

We need a notation to supply the two related operands "$\underline{set}(obj)$" and "$(obj \rightarrow geo_1)$".

Q3: Determine the city or cities closest to Hagen.

  (a) cities **select**[cname ≠ "Hagen"] Hagen **closest**[center]

  (b) **closest** Hagen
      column center
      from cities
      where cname ≠ "Hagen"

In this example, "cities" corresponds to the "$\underline{set}(obj)$" and "center" to the "$(obj \rightarrow geo_1)$" operand. In geo-relational algebra first the set of objects is written and then the *points* value (the "geo_2" operand); the attribute is given separately in brackets. For an extended SQL we suggest to introduce a "**column** α **from** β" construct to denote a set of objects β with an attribute α. This construct should be viewed as returning the two operands separately as they are needed by the ROSE algebra. In contrast, writing "**select** α **from** β" would yield a set (or multiset) of attribute values, that is, an operand of type $\underline{set}(geo_1)$. This is not what the operator needs; in fact, a set of values is not even available in the ROSE type system given below.

Extend objects by derived (attribute) values. This is needed to make the results of spatial operations available. In geo-relational algebra this is provided by the **extend** operator, in SQL by expressions in the select-clause, as in query Q1.

Allow naming of an SDT value or a new attribute. We have already seen two instances of this. In query Q2 a name (Hagen) was assigned to an SDT value. An attribute name must also be provided for derived attributes, as in query Q1. Finally, new attribute names are needed by operations that construct new objects such as **decompose**.

Q4: Decompose all states into their basic areas.

  (a) states **decompose**[territory {basic_area}]

  (b) **decompose into column** basic_area
     column territory
     from states

Here (a) shows the style for naming the new attribute that would be used in geo-relational algebra (although there was no **decompose** operator). For the extended SQL we have invented an "**into column** α" construct for the same purpose.

Offer a grouping operation. This is needed to support a "fusion" operation (which essentially groups a collection of objects and forms the union of the areas in each group).

Q5: Determine all regions of the states speaking the same language.

  (a) states **fusion**[language; territory]

  (b) **fusion** territory
     from states
     group by language

These applications of the fusion operator are really abbreviations of the use of grouping:

  (a) states **group_by**[language; group **sum**[territory]]

  (b) **select sum**(territory)
     from states
     group by language

In geo-relational algebra and in SQL such a grouping operation is available; it is used together with a **sum** aggregate function of the ROSE algebra. There may be several attributes for grouping and several aggregate expressions.

7 The ROSE Algebra

We are now ready to define the ROSE algebra itself (ROSE stands for RObust Spatial Extension). It is a *realm-based algebra*, since data types are defined on realms and since operations operate on and produce realm-based spatial values. All values occurring as operands are assumed to be defined over the *same* realm.

Defining the ROSE algebra means that we will give a second-order signature with the types *points*, *lines*, and *regions* as well as types of the object model interface. The algebra then consists of carrier sets for the types and functions for the operations. The carrier sets for the three spatial types have already been defined in Section 4. In this section we formally define the functions for all operations.

The type system of the ROSE algebra, as discussed in Sections 5 and 6, is summarized in the following specification:

kinds IDENT, DATA, EXT, GEO, OBJ, SET
type constructors

	$\rightarrow$ IDENT	*ident*
	$\rightarrow$ DATA	*int*, *real*, *bool*, ...
	$\rightarrow$ EXT	*lines*, *regions*
	$\rightarrow$ GEO	*points*, *lines*, *regions*
OBJ	$\rightarrow$ SET	*set*

Kind DATA describes the (standard) data types of the object model interface; there will be other types in addition to the three that are required. There is a kind EXT just containing types *lines* and *regions* which supports the definition of operations not suitable for *points*.

The operations of the ROSE algebra are divided into four groups. For each group we give an informal introduction, show the signature, and then define the semantics of the operations.

7.1 Spatial Predicates

These operations compare two spatial values with respect to their topological relationships and return a boolean value. The predicates' names are self-explanatory.

$\forall$ *geo* in GEO. $\forall$ *ext*, *ext$_1$*, *ext$_2$* in EXT. $\forall$ *area* in *regions* $^{area\text{-}disjoint}$.

geo $\times$ *geo*	$\rightarrow$ *bool*	=, $\neq$, **disjoint**
geo $\times$ *regions*	$\rightarrow$ *bool*	**inside**
regions $\times$ *regions*	$\rightarrow$ *bool*	**area_disjoint**, **edge_disjoint**,
		edge_inside, **vertex_inside**
ext$_1$ $\times$ *ext$_2$*	$\rightarrow$ *bool*	**intersects**, **meets**
area $\times$ *area*	$\rightarrow$ *bool*	**adjacent**, **encloses**
points $\times$ *ext*	$\rightarrow$ *bool*	**on_border_of**
ext$_1$ $\times$ *ext$_2$*	$\rightarrow$ *bool*	**border_in_common**

For each operator **op** of the ROSE algebra we define a function f_{op} which gives the operator's semantics and which has domains and codomain according to the operator's signature entry. An underlying realm R is assumed in all definitions. Of course, we rely on the primitives introduced in Sections 3 and 4.

Let v_1, v_2 be two values of the same type in GEO. Then

$$f_=(v_1, v_2) := (v_1 = v_2)$$
$$f_{\neq}(v_1, v_2) := (v_1 \neq v_2)$$
$$f_{disjoint}(v_1, v_2) := (v_1 \text{ and } v_2 \text{ are } \textbf{\textit{disjoint}})$$

Let v be a value of a type in GEO and F be a value of type *regions*.

$$f_{inside}(v, F) := (v \textbf{ \textit{inside}} F)$$

Let v_1, v_2 be each either a *lines* or a *regions* value.

$f_{\textbf{intersects}}(v_1, v_2) := (v_1 \text{ and } v_2 \ \textbf{\textit{intersect}})$

$f_{\textbf{meets}}(v_1, v_2) := (v_1 \text{ and } v_2 \ \textbf{\textit{meet}})$

Let F and G be two <u>*regions*</u> values of a subtype *area* in <u>*regions*</u> $^{\textit{area-disjoint}}$.

$f_{\textbf{adjacent}}(F, G) := (F \text{ and } G \text{ are } \textbf{\textit{adjacent}})$

$f_{\textbf{encloses}}(F, G) := (F \ \textbf{\textit{encloses}} \ G)$

The remaining definitions are omitted; they all just lift spatial algebra primitives to the ROSE level.

7.2   Operators Returning Spatial Data Type Values

The second group of operations consists of *operators returning atomic spatial values* as results. The operators **intersection**, **plus**, and **minus** realize the closure properties of the ROSE algebra with respect to intersection, union, and difference of two atomic spatial values. The **common_border** operator finds the common boundary line(s) of two <u>*regions*</u> or <u>*lines*</u> values. The **vertices** operator returns the vertex (corner) points of a <u>*lines*</u> or <u>*regions*</u> value and produces a <u>*points*</u> value. The **contour** operator calculates a <u>*lines*</u> value from a <u>*regions*</u> value's boundary. The **interior** operator is applied to a <u>*lines*</u> value and yields a <u>*regions*</u> value which is composed of all regions that are enclosed by segments of the <u>*lines*</u> value. If F is a <u>*regions*</u> value, **interior**(**contour**(F)) can be used to remove all holes of F; both operators are not inverse to each other.

$\forall \ geo$ in GEO. $\forall \ ext, ext_1, ext_2$ in EXT.

<u>*points*</u> $\times$ <u>*points*</u>	$\rightarrow$	<u>*points*</u>	**intersection**
<u>*lines*</u> $\times$ <u>*lines*</u>	$\rightarrow$	<u>*points*</u>	**intersection**
<u>*regions*</u> $\times$ <u>*regions*</u>	$\rightarrow$	<u>*regions*</u>	**intersection**
<u>*regions*</u> $\times$ <u>*lines*</u>	$\rightarrow$	<u>*lines*</u>	**intersection**
$geo \times geo$	$\rightarrow$	geo	**plus, minus**
$ext_1 \times ext_2$	$\rightarrow$	<u>*lines*</u>	**common_border**
ext	$\rightarrow$	<u>*points*</u>	**vertices**
<u>*regions*</u>	$\rightarrow$	<u>*lines*</u>	**contour**
<u>*lines*</u>	$\rightarrow$	<u>*regions*</u>	**interior**

Note that the **intersection** operator applied to two <u>*lines*</u> values does not yield a <u>*lines*</u> value as the set-theoretic intersection of the underlying segment sets (see operator **common_border**) but a <u>*points*</u> value.

Let P and Q be two <u>*points*</u> values, K and L be two <u>*lines*</u> values, and F and G be two <u>*regions*</u> values.

$f_{\textbf{intersection}}(P, Q) := \textbf{\textit{intersection}}(P, Q)$

$f_{\textbf{intersection}}(K, L) := \{p \in R \mid \exists \, s \in S(K) \, \exists \, t \in S(L) : s \text{ and } t \ \underline{meet} \text{ in } p \wedge p \text{ is not a meeting point}\}$

$f_{\textbf{intersection}}(F, G) := \textbf{\textit{intersection}}(F, G)$

$f_{\textbf{intersection}}(F, L) := blocks(\{s \in S(L) \mid \exists \, f \in F : s \ \underline{inside} \ f\})$

Let v_1 and v_2 be both either two *points* values, two *lines* values, or two *regions* values.

$$f_{\textbf{plus}}(v_1, v_2) := \textbf{\textit{union}}(v_1, v_2)$$
$$f_{\textbf{minus}}(v_1, v_2) := \textbf{\textit{difference}}(v_1, v_2)$$

Let K and L be two *lines* values and F and G be two *regions* values.

$$f_{\textbf{common\_border}}(K, L) := \textbf{\textit{intersection}}(K, L)$$
$$f_{\textbf{common\_border}}(F, L) := f_{\textbf{common\_border}}(L, F) := blocks(S(F) \cap S(L))$$
$$f_{\textbf{common\_border}}(F, G) := blocks(S(F) \cap S(G))$$

Let v be a *lines* or *regions* value.

$$f_{\textbf{vertices}}(v) := \{p \in R \mid \exists\, s \in S(v) : s = (p, q)\}$$

Let $F = \{f_1, ..., f_n\} = \{(c_1, H_1), ..., (c_n, H_n)\}$ be a *regions* value.

$$f_{\textbf{contour}}(F) := blocks(\bigcup_{i=1}^{n} S(c_i))$$

Let L be a *lines* value.

$$f_{\textbf{interior}}(L) := regions(\bigcup_{c\, \in\, cycles\,(S(L))} S(c) - \{s \in S(L) \mid \exists\, c \in cycles(S(L)) : s\ \underline{edge\text{-}inside}\ c\})$$

Forming the interior of a *lines* value L is a somewhat more complex operation. First, the union of all segments is computed that occur in any cycles that can be formed from the segments of L. From this set of segments all segments are removed that lie properly within (*edge-inside*) some cycle. Hence only segments of "outer cycles" remain. Since these segments describe a set of edge-disjoint R-faces, the *regions* function can be applied to return a corresponding *regions* value.

7.3   Spatial Operators Returning Numbers

The third group of operations contains *spatial operators returning numbers*. The **no_of_components** operator yields the number of components (R-points, R-blocks, or R-faces) of a spatial value. The **dist** operator calculates the minimal distance between any two spatial values. The **diameter** of a spatial value is defined as the largest distance between any of its components. The **length** operator calculates the length of all segments of a *lines* value. The **area** operator computes the sum of the areas of all faces of a *regions* value. The **perimeter** operator calculates the sum of the length of all cycles of a *regions* value. If we intend to compute only the sum of the length of the outer cycles and not of the holes of a *regions* value, we can use the **contour** operator to eliminate holes first.

$\forall\ geo, geo_1, geo_2$ in GEO.

geo	$\rightarrow$ *int*	**no_of_components**
$geo_1 \times geo_2$	$\rightarrow$ *real*	**dist**
geo	$\rightarrow$ *real*	**diameter**
lines	$\rightarrow$ *real*	**length**
regions	$\rightarrow$ *real*	**area**, **perimeter**

Let v and w be values of types in GEO. Let L be a <u>*lines*</u> value and F be a <u>*regions*</u> value.

$$f_{\textbf{no\_of\_components}}(v) := card(v)$$

$$f_{\textbf{diameter}}(v) := max\{\underline{dist}(p, q) \mid p, q \in f_{\textbf{vertices}}(v)\}$$

$$f_{\textbf{length}}(L) := \sum_{s \in S(L)} \underline{length}(s)$$

$$f_{\textbf{area}}(F) := \sum_{f \in F} \underline{area}(f)$$

$$f_{\textbf{perimeter}}(F) := \sum_{s \in S(F)} \underline{length}(s)$$

Note that the four operators **diameter**, **length**, **area**, and **perimeter** are not invariant against redrawing, i.e., each of these four operations applied before and after a necessary redrawing of one or more segments of a <u>*lines*</u> or <u>*regions*</u> value will yield slightly different results. We want to define the **dist** operator in a way that is invariant against redrawing, since it has besides a numerical aspect also a topological one. Consider a set of spatial objects with a spatial attribute and a spatial reference value for which the nearest spatial object has to be computed. If the distance calculations between spatial reference value and spatial attribute value vary depending on possible redrawings, the answer regarding the nearest spatial object may vary, too, and lead to topological inconsistency. Note the relationship to the **closest** operator discussed below. Therefore we define the distance function as follows. GP will denote the set of grid points associated with a spatial value.

For a <u>*points*</u> value v let $GP(v) := v$, for a <u>*lines*</u> value v let $GP(v) := E(S(v))$ (the union of the envelope points of all segments of v), and for a <u>*regions*</u> value v let $GP(v) := E(S(v)) \cup P_{in}(v)$. Then

$$f_{\textbf{dist}}(v, w) := \begin{cases} 0, & \text{if } GP(v) \cap GP(w) \neq \varnothing \\ min\{\underline{dist}(p, q) \mid p \in GP(v), q \in GP(w)\} & \text{otherwise} \end{cases}$$

Although the sets of grid points used in the definition may be very large, this operation can be efficiently implemented, since it can be reduced to distance computations between a point p and a segment s. There it is only necessary to consider those envelope points that are neighbours of the intersection point of s with a perpendicular line going through p.

7.4 Spatial Operators on Sets of Objects

Operators of the last group take *sets of objects* as operands; some of them create new sets of objects as a result. The **sum** operator aggregates over the values of some spatial attribute of an object set and computes the geometric union of all these values. The **closest** operator yields that object of an object set whose spatial value is nearest to a spatial reference value. The **decompose** operator was already explained in Section 6.2; it multiplies each object of an object set according to the number of components of its spatial attribute value and adds this component as a new attribute. The **overlay** operator allows to superimpose one partition of the plane on another one and to combine them into area-disjoint regions. As described in Section 5.2, partitions are given as sets of objects with an attribute of a type in <u>*regions*</u> ^{*area-disjoint*}. The resulting set of objects contains one object for each new region obtained as the intersection of a region of the first partition with a region of the second partition.
Figure 15: Overlaying two partitions of the plane

Note that it is not required that the plane is covered completely by the regions of a partition. Thus it is possible that a region of the first partition does not intersect any region of the second partition. In this case it will not be part of any new object[6] (Figure 15).

The **fusion** operator merges the values of a specified (set of) spatial attribute(s) on the basis of the equality of the values of another (set of) non-spatial attribute(s). For each group of equal non-spatial attribute values a (set of) new spatial value(s) is created as the geometric union of a set of spatial values of the group[7]. In Figure 16, a partition of districts with their land use is given. The task is to compute the regions with the same land use. Neighbour districts with the same land use are replaced by a single region, that is, their common boundary line is erased. Each of the hatched areas on the left is part of an object describing a district. On the right after the application of the **fusion** operator all areas belonging to the same group g_i form *a single regions* value and are hatched in the same way.

The signature for these operations is as follows:

$\forall$ *obj*, *obj*$_1$, *obj*$_2$ in OBJ. $\forall$ *geo*, *geo*$_1$, *geo*$_2$ in GEO. $\forall$ *area*$_1$, *area*$_2$ in *regions* $^{area\text{-}disjoint}$.
$\forall$ *data*$_i$ in DATA. $\forall$ *geo*$_j$ in GEO.

$set(obj) \times (obj \rightarrow geo)$	$\rightarrow \ geo$	**sum**
$set(obj) \times (obj \rightarrow geo_1) \times geo_2$	$\rightarrow \ set(obj)$	**closest**
$set(obj) \times (obj \rightarrow geo) \times ident$	$\rightarrow \ set(o: \text{OBJ})$	**decompose**
$set(obj_1) \times (obj_1 \rightarrow area_1) \times set(obj_2) \times (obj_2 \rightarrow area_2) \times ident$		
	$\rightarrow \ set(o: \text{OBJ})$	**overlay**
$set(obj) \times (obj \rightarrow data_i)^+ \times (obj \rightarrow geo_j)^+$	$\rightarrow \ set(o: \text{OBJ})$	**fusion**

Since the operations of this group deal with sets of objects, for their semantics definition the concepts of the object model interface are needed.

---

[6] This corresponds to the standard join operation. If regions of one partition not intersecting a region of the other partition were in the result, it would be similar to an outer join.

[7] The **fusion** operator could be extended to allow grouping also by spatial attributes. For efficient implementation this requires a capability of sorting by spatial data type values, which means the ROSE algebra would have to provide a "less-than" operator for each of the three SDTs imposing a linear order.
Figure 16: Merging a partition of districts concerning the same land use

For the definition of the **sum** operator let $O = \{o_1, ..., o_n\}$, for $n \geq 0$, be the operand set of objects and *attr* the attribute function yielding an SDT value for each object.

$$f_{\mathbf{sum}}(O, attr) := \begin{cases} \mathbf{\textit{union}}(...(\mathbf{\textit{union}}(attr(o_1), attr(o_2)), ...), attr(o_n)) & \text{if } O \neq \varnothing \\ \varnothing & \text{otherwise} \end{cases}$$

For the definition of the **closest** operator let O be the set of objects, *attr* the attribute function, and *rv* the reference value for which the nearest spatial value has to be calculated. Then

$$f_{\mathbf{closest}}(O, attr, rv) := \{o \in O \mid \forall \, o' \in O : f_{\mathbf{dist}}(rv, attr(o)) \leq f_{\mathbf{dist}}(rv, attr(o'))\}$$

The **decompose** operator has an unspecified result type in OBJ; hence in addition to its semantics function $f_{\mathbf{decompose}}$ it needs a type mapping $\tau_{\mathbf{decompose}}$, as described in Section 5.1. When an operator **alpha** with a type mapping is used in a query and applied to some operands (say **alpha**(a, b, c)), then this will lead to a call of its semantics function $f_{\mathbf{alpha}}(a, b, c)$ during query execution. Additionally it will lead to a call of the type mapping function $\tau_{\mathbf{alpha}}$ during query parsing; the type mapping function is called not with the actual operands (i.e., a, b, c) but instead with *the actual types of these operands*. These types can vary because of the polymorphic specification of operators which is the reason why type mappings are needed at all. The only exception to this rule are operands of type *ident*; for them not the type *ident* but the actual identifier is passed to the type mapping function. This is because the main purpose of such operands is the use in type mappings.

$$f_{\mathbf{decompose}}(O, attr, name) := \{o \oplus v \mid o \in O, v \in attr(o)\}$$

$$\tau_{\mathbf{decompose}}(\underline{set}(obj), (obj \rightarrow geo), name) := obj \oplus (name, geo)$$

Hence each object is extended by one of the components of its spatial attribute; the new object type is an extension of the operand object type by a new attribute *name* of type *geo*. For example, the call in query Q4 (Section 6.2) "**decompose**(states, territory, basic_area)"would lead to the following calls

of semantics function and type mapping:

$$f_{\textbf{decompose}}(states,\ territory,\ basic\_area)$$
$$\tau_{\textbf{decompose}}(\underline{set}(state),\ (state \rightarrow \underline{regions}),\ basic\_area)$$

The **overlay** operator also needs a type mapping:

$$f_{\textbf{overlay}}(O_1,\ attr_1,\ O_2,\ attr_2,\ name)$$

$$:= \{(o_1 \otimes o_2) \oplus v \mid \exists\, o_1 \in O_1\ \exists\, o_2 \in O_2 :$$

$$f_{\textbf{intersects}}(attr_1(o_1),\ attr_2(o_2)) = true \wedge v = f_{\textbf{intersection}}(attr_1(o_1),\ attr_2(o_2))\}$$

$$\tau_{\textbf{overlay}}(\underline{set}(obj_1),\ (obj_1 \rightarrow area_1),\ \underline{set}(obj_2),\ (obj_2 \rightarrow area_2),\ name)$$

$$:= (obj_1 \otimes obj_2) \oplus (name,\ new(\underline{regions}^{\,\textit{area-disjoint}}))$$

Here the resulting object type is the product of the two operand types extended by a new attribute *name* of a new type in the kind $\underline{regions}^{\,\textit{area-disjoint}}$.

The **fusion** operator is not formally defined since it is only an abbreviation of a corresponding grouping operation, as described in Section 6. The semantics definition would rely on a formalization of the semantics of the grouping operation.

8 Integration with a DBMS Query Language: O$_2$SQL/ROSE

The purpose of this section is two-fold: (i) We show the integration of the ROSE algebra with one particular data model and query language, which further illustrates the concepts and requirements of the object model interface. (ii) We demonstrate the "expressive power" of the ROSE algebra (within the context of a query language) by showing some example queries.

For the integration example we select O$_2$ as one of the state-of-the-art object-oriented database systems with O$_2$SQL as its current and future standard query language [Ba89, BaCD89, BaDK92, O$_2$93]. O$_2$SQL is a functional language that deals with and allows to construct atomic values, tuples, sets and lists, provides operations on these structures, and allows one to define methods on classes. Flat as well as nested structures can be constructed, and all levels of a structure can be accessed. Elements of sets and lists and components of tuples may be of any type or class. The syntax of O$_2$SQL has an SQL-like style through a *select-from-where* construct corresponding to the three algebraic operations projection, cartesian product, and selection, extended by object-oriented features.

In the sequel we demonstrate the integration of our ROSE algebra with O$_2$SQL by presenting example queries. The notations regarding class definitions and queries comply with the notations in [BaDK92, O$_2$93]. A few notational extensions are necessary. Examples are based on the following simple database which models spatial aspects of Germany. The keyword **public** means that components of a tuple structure are "visible" and can be accessed.

> **class** State
>   **public type tuple** (name : $\underline{string}$, territory : $\underline{regions}$)
> **end;**

class City
    public type tuple (name : *string*,
                    zipcode : *integer*,
                    statistical_data : **tuple** (foundation_date : *integer*,
                                            population : *integer*,
                                            unemployment_rate : *real*),
                    municipal_area : *regions*)
    end;
class Highway
    public type tuple (number : *string*, way : *lines*)
    end;
class River
    public type tuple (name : *string*, route : *lines*)
    end;
class District
    public type tuple (name : *string*, region : *regions*, land_use : *string*)
    end;

A class is a description of a group of objects but not a persistent repository for them in a database. In O_2 only objects associated with names are persistent. We therefore introduce for each class a named collection of objects:

name Cities : **set**(City); **name** States : **set**(State); **name** Highways : **set**(Highway);
name Rivers : **set**(River); **name** Districts : **set**(District);

Spatial attributes are defined in the same way as attributes of standard data types, using the SDTs of the ROSE algebra. Note however, that we have compromised on the typing of *regions* attributes. In the example database, each of these attributes should really have its own type *area$_i$* within the kind *regions$^{area\text{-}disjoint}$* in order to be able to model partitions of the plane. Such a sophisticated typing is not available in O_2. We will therefore assume that for the O_2 integration the definition of the ROSE algebra is slightly changed so that all operators defined on *area$_i$* types are defined on *regions* instead. This does not change the definition of syntax or semantics of these operators because any value of some type *area$_i$* in *regions$^{area\text{-}disjoint}$* is in fact a *regions* value; it just means that type checking cannot ensure any more that they are applied to partitions.

The syntax of the spatial operations of the ROSE algebra in a query language is not prescribed by the signature of the operations but is part of the process of embedding the operations into the desired query language, i.e., dependent on the extended query language. Here, we select infix syntax for spatial predicates and the two operations **plus** and **minus** and a functional syntax for all other operations.

Q1:   List the names and the land use of districts which are neighbors with the same land use.

    select   **tuple** (dname1: d1.name, dname2: d2.name, land_use: d1.land_use)
    from   d1 **in** Districts,
             d2 **in** Districts
    where   d1.region **adjacent** d2.region **and** d1.land_use = d2.land_use

All spatial predicates of the ROSE algebra (first group of spatial operations) can be used as selection criteria in the where clause, just like conventional predicates. The result of this query is a set of tuples each formed by the tuple constructor *tuple*. Components of tuples are accessed by the field extraction operator denoted by a dot. Hence here we have the facility of the OMI: *Denote a data type value (within an object set iteration).*

Q2: Which states are enclosed by which other states?

> **select**   **tuple** (state1: s1, state2: s2)
> **from**   s1 **in** States,
>   s2 **in** States
> **where**   s1.territory **encloses** s2.territory

The result of the query is a set of tuples, each tuple being a pair of *State* objects.

Q3: Determine which highways cross which rivers and list their names, their geometries and their crossings.

> **select**   **tuple** (name: r.name, route: r.route, number: h.number, way: h.way,
>   crossing: **intersection** (r.route, h.way))
> **from**   r **in** Rivers,
>   h **in** Highways
> **where**   r.route **intersects** h.way

Each tuple of the query result contains an attribute 'crossing' whose value is the intersection of a river and a highway value. (OMI: *Extend objects by derived attribute values, allow naming of a new attribute*.)

Q4: Associate with each state those cities lying inside that state.

> **select**   **tuple** (state: s, cities_in_state: **select** c
>   **from** c **in** Cities
>   **where** c.municipal_area **inside** s.territory)
> **from**   s **in** States

The result is a set of tuples, each tuple being a pair of a *State* object and a set of *City* objects whose geometry lies inside the geometry of the *State* object.

Q5: Which rivers form partially the boundary line of which states? In which parts do they agree?

> **select**   **tuple** (rname: r.name, sname: s.name, border: **common_border** (s.territory, r.route))
> **from**   s **in** States,
>   r **in** Rivers
> **where**   s.territory **border_in_common** r.route

Q6: Compute the length of the river and highway network.

> **length** (**sum** (**select attribute** way **from** h **in** Highways)
>   **plus sum** (**select attribute** route **from** r **in** Rivers))

Here we have introduced a first extension to O_2SQL to fulfill the requirement of the OMI: *Denote a collection of objects together with an attribute*. The notation is "**select attribute** *attr* **from** *s* **in** *S*"

where *attr* is the name of the attribute and *S* the set of objects.[8] This is analogous to the "**column** α **from** β" construct discussed in Section 6.2.

It is interesting to observe that in this query first a single *lines* value is formed to which then the length function is applied. Using the **sum** aggregate function of O_2 applicable to sets of reals, one might formulate the query as follows:

> **sum** (**select length**(h.way) **from** h **in** Highways) +
> **sum** (**select length**(r.route) **from** r **in** Rivers)

Actually the result will only be the same if no two highways use the same piece of the highway network. But a more important issue to be discussed here is the view of aggregate functions. The **sum** aggregate function of O_2 used in this last example is applied to a *set of values*. In contrast, the only aggregate function of the ROSE algebra (**sum**) is applied to a *set of objects with a spatial attribute*. The rationale behind this is to keep the type system of the object model interface as simple as possible. For example, in the relational model sets of values are not available. The ROSE algebra only assumes that collections of objects and atomic values exist.

Q7: Calculate the perimeter of Bavaria (class *State* is assumed to describe states within Germany).

> **perimeter** (**element** (**select** s.territory **from** s **in** States **where** s.name = "Bavaria"))

The O_2SQL *element* operator extracts the unique element of a singleton set. This is exactly the facility "*denote a data type value (without object set iteration)*" of the OMI. The expression "**element** ..." denotes the territory of Bavaria.

Q8: Calculate the region outside Bavaria where wheat is cultivated.

> **sum** (**select**   **attribute** region
>   **from**   d **in** Districts
>   **where**   d.land_use = "wheat")
> **minus**
> **element**   (**select**   s.territory
>   **from**   s **in** States
>   **where**   s.name = "Bavaria")

This query yields an atomic spatial value.

Q9: Determine all cities that are located in areas which are completely enclosed by highways.

> **select**   c
> **from**   c **in** Cities
> **where**   c.municipal_area **inside interior** (**sum** (**select attribute** way **from** h **in** Highways))

This query yields a set of *City* objects fulfilling the where condition.

Q10: Check if the highways form a connected network.

> **no_of_components** (**sum** (**select attribute** way **from** h **in** Highways)) = 1

---

[8]   For the SQL embedding in Section 6.2 we have used a keyword "column". This seemed to fit with SQL which also speaks of "tables" rather than relations. For O_2 which uses terms like "tuple", a keyword "attribute" appears adequate. Of course, this is just a matter of taste.

Q11: List the name(s) of the highway(s) being closest to Munich.

> **define** Munich **as**
> **element** (**select** c.municipal_area **from** c **in** Cities **where** c.name = "Munich");
>
> **select** h.number
> **from**   h **in closest** (**select attribute** way **from** h **in** Highways, Munich)

In the first step a *named query* of O_2 defines Munich as a *regions* value. This is the facility " *allow naming of an SDT value*" of the OMI. The **closest** operator takes as operands a class or any other homogeneous set of objects together with a spatial attribute defined on that object type, and a spatial reference value (in this case Munich). It returns a set of objects which can be used in a query at all those positions where a set expression is allowed.

Q12: Determine the component regions of the state Schleswig-Holstein (which consists of a main land area as well as several islands in the North Sea).

> **select** s.component
> **from**   s **in**
>   **decompose into** component
>   **select attribute** territory
>   **from** s **in** States
>   **where** s.name = "Schleswig-Holstein"

The **decompose** operator has three arguments: a class or any other homogeneous set of objects, an SDT attribute to be decomposed, and a name for the new attribute resulting from decomposition. The query yields a set of *regions* values. Here we have introduced a second extension to O_2SQL to offer the facility "*allow naming of a new attribute*" of the OMI, using a phrase "**into** *attr*", as in Section 6.2.

Q13: Partition the state Bavaria with respect to the districts of land use.

> **overlay into** districts_within_Bavaria
> (**select attribute** territory **from** s **in** States **where** s.name = "Bavaria",
> **select attribute** region **from** d **in** Districts)

The result is a set of objects with a new attribute "districts_within_Bavaria". Each partition for the overlay is given as a set of objects with a *regions* attribute.

Q14: Compute the regions of the same land use.

> **fusion** (Districts; land_use; region)

The **fusion** operator requires three arguments which are syntactically separated by semicolons: a set of objects, a list of non-spatial attributes used for grouping, and a list of spatial attributes used for geometric union. In the query above the *District* objects are grouped according to equal land use and for each group the geometric union of the *regions* values of the "region" attribute is formed.

O_2SQL offers a grouping operator **group** so that the query can be formulated without an explicit **fusion** operator:

      group   d **in** Districts **by** (land_use: d.land_use)
      with   (region: **sum** (**select attribute** p.region **from** p **in partition**))

Here the **group** operator is applied to a set of *District* objects. It groups *District* objects by values of their "land_use" attribute and produces for each group one result tuple with two attributes. The first attribute "land_use" receives the value of the "land_use" attribute of the group; the second attribute "region" is determined in the **with**-clause by an expression which computes for each group the geometric union of the "region" attribute values. One can refer to the current group by a keyword **partition**.

9 Conclusions

In this paper and the companion paper [GüS93] we have defined the ROSE algebra, a system of realm-based spatial data types. After the geo-relational algebra [Gü88a] which was implemented in the Gral system[9] [Gü89, BeG92] this is a second attempt to define a spatial algebra for database systems and in some sense it represents what we have learned in the meantime. In closing, let us summarize the highlights of the ROSE algebra. It may also be interesting to compare to the geo-relational algebra (in the sequel geo-algebra for short).

General types and operations. The ROSE algebra has very general data types to represent points, lines, and regions in the plane. For example, it is now possible to represent the whole area of a state including islands or separate land areas in a single <u>*regions*</u> value, or a complete highway network in a single <u>*lines*</u> value. On the one hand, this generality makes the spatial objects and operations conceptually more difficult, requires a quite elaborate system of definitions, and also needs more effort in the implementation. This is why in the geo-algebra a decision was made to deal only with simple polygons and single-component objects. On the other hand, the generality is needed in applications (with Gral this became obvious when the German state of Niedersachsen had to be represented which encloses - as a hole - the state of Bremen). We feel that through the several layers of definitions of the ROSE algebra we have managed the complexity. Apart from the better capability to model spatial objects, an important benefit is that the types are now closed under set operations of the underlying point sets - for any type one can form union, difference (**plus**, **minus**) or aggregate over its values (**sum**) which makes the rather complex fusion operation [ScV89, GaNT91] a simple by-product of grouping. Also, all operations are now defined in the most general way (e.g. the **closest** operation is available for all spatial types). In contrast, in the geo-algebra it was not possible to define a difference operator on regions since it would have led to holes, and intersection had to be defined as a relation operation because a resulting set of intersection values could not be represented as a single SDT value.

Rigorous definition. The carrier sets of the types and the semantics of all operations have been defined completely, down to the level of simple arithmetic primitives on integers. As a result, there is no ambiguity for a programmer about the precise meaning of operations or about allowed structures. We feel this is very important because when dealing with complex spatial structures invariably questions about special cases come up like "Is it allowed that the boundary of a hole in a region touches the outer

---

[9] The second author took part in this implementation effort.

boundary?" or "Qualify two adjacent regions as intersecting?" The ROSE algebra definition gives precise answers to all such questions to an implementor and, if not to end users, at least to people writing manuals for end users.

Numerical robustness, finite resolution. The underlying realm provides the ROSE algebra with a discrete basis and shields it from all problems of numerical robustness. Integer coordinates can be used for the representation of SDT values; critical operations like testing whether points lie on the border of regions become feasible. In contrast, in the geo-algebra operations like **meets** or **common_border** were omitted, because - with real numbers representing coordinates of SDT values - it was not clear how these operations could be implemented in a numerically robust way. The discrete basis also greatly simplifies the implementation of geometric algorithms for the operations. For example, to implement **common_border** one can keep for each *lines* or *regions* value its defining segments in (x, y)-lexicographic order and then simply scan the two lists in parallel. Many operations can be implemented by plane-sweep algorithms [NiP82, BeO79] which are simplified here because no intersection points need to be computed; all sweep stations are known beforehand and one does not need a dynamic structure to maintain the ordered list of sweep stations.

Data model independence, clean object model interface. The ROSE algebra is not tied to any particular data model but can cooperate with many models and query languages. This might have been achieved in a trivial way by omitting all operations manipulating objects (like **closest**, **overlay**) and not caring how the results of geometric operations can be used in the DBMS. Instead, we have defined an object model interface and investigated quite carefully the issues arising with the integration of the ROSE algebra into a query language. Section 8 has demonstrated that a nice integration with, for example, an object-oriented model and query language can be achieved. To our knowledge, this is the first time that the problem of interfacing a general purpose query language with a complex application-specific sublanguage has been examined in some detail. Such interfaces will be important for cooperative database systems using external computation services [ScW91].

Open Problems and Future Work

Implementation of the ROSE algebra. Data structures for the three SDTs and procedures for all operations except for **dist** and the set-manipulating operations of the last group (Section 7.4) have been realized [Ri94] and are available as a module library written in Modula-2. The implementation of operations makes heavy use of the following three techniques: (i) scan or parallel scan of the *halfsegment sequence*[10] of one or two objects, (ii) plane-sweep, and (iii) graph algorithms [Ri94]. Algorithms and practical aspects of the implementation will be described in a forthcoming paper [GüRS95]. As a next step, we plan to encapsulate this implementation within a "data type extension package" and then to connect it to the Gral system as well as to another query processor called SECONDO.

A component that allows to represent a realm and which offers realm operations (updates with redrawing, described in [GüS93]) is almost finished. The points and segments of a realm are stored in an LSD-tree [HeSW89]. For the problems of interfacing realms and database systems see [GüS93].

---

[10] For a *lines* or *regions* value, its *halfsegment sequence* contains each segment of the object twice, once for the left and once for the right end point, called the *dominating point* for this segment. The halfsegment sequence is ordered xy-lexicographically by dominating points.

Some problems remain with the realm-based approach and need to be further investigated:

Invariance under redrawing. We are not satisfied with the fact that some of the numeric ROSE operations (**length**, **area**, etc.) yield slightly different results before and after a redrawing due to an update of the realm. Whereas we feel that slight numerical errors are tolerable in contrast to topological errors, this may also lead to "discrete errors". For example, when a collection of objects is sorted by area of its regions, the order may change through a realm update. Perhaps a definition of these operations can be found that is sufficiently consistent with the geometry of the objects, but invariant under redrawing.

Objects and operations violating realm closure. One is still interested in spatial objects that are not part of the given realm. For example, it should be possible to draw interactively a region and then to use it in a query. The new region cannot directly be compared with realm-based objects. One possible strategy might be to insert this region temporarily into the realm and to remove it again when the query has been processed. There may be other solutions. We have so far restricted attention to operations that are closed with respect to the underlying realm, but there are also interesting operations that leave the given realm, for example, construction of a Voronoi diagram, a convex hull, or of a buffer zone around a spatial object. One should study how these can be accommodated. One strategy might be to create a new realm for the new spatial values, select a set of SDT values in the database that might interact with the new geometries and create another "small" realm for them, and then use a "merge" operation on realms to compute all intersections.
